ABSTRACT

We report synthesis windows for growth of millimeter-long ZnTe nanoribbons and ZnSe nanowires using vapor transport. By tuning the local conditions at the growth substrate, high aspect ratio nanostructures can be synthesized. A Cu-ion immersion doping method was applied, producing strongly p-type conduction in ZnTe and ionic conduction in ZnSe. These extreme aspect ratio wide-bandgap semiconductors have great potential for high density nanostructured optoelectronic circuits.

KEYWORDS

Aspect ratio, doping, nanowires, zinc selenide, zinc telluride

Introduction

Nanostructures, in particular "one-dimensional" structures such as nanowires and nanoribbons, present a useful materials platform for exploring quantum effects and fabricating novel devices at high densities. Free-carrier doping is needed for most of these applications. Typically, doping in nanowires is achieved by *in situ* incorporation of dopants during growth of the nanowires [1, 2]. For a wide range of nanowire device applications such as inversion-mode transistors, avalanche photodiodes, light emitting diodes, and tunneling field-effect transistors, axially modulated doping is needed to accomplish or optimize their functionalities. Although axial modulation of doping profiles can be achieved *in*

situ [3], accurate alignment and positioning of the appropriately doped regions of the nanowires to build functional devices are complex and challenging. *Ex situ* doping can avoid these complications by introducing specific dopants into lithographically-defined regions after the nanowires are grown [4–6] or even after the devices are assembled [7].

ZnSe and ZnTe, with direct bandgaps at 2.65 and 2.25 eV, respectively, are ideally situated on the optical spectrum for green-blue optical devices as well as other optoelectronic applications [8, 9]. ZnSe nanowires can also be used as nanoscale optical cavities [10]. Undoped nanowires of ZnSe and ZnTe with strong band-edge and defect luminescence have been grown by vapor transport and other methods [10–14]. Intentional doping of nanowires

Address correspondence to wuj@berkeley.edu

of these compounds is less common. For compound semiconductors, the overall stoichiometry must be regulated in addition to incorporating and activating dopants, making *in situ* doping a non-trivial task. Doping of ZnTe and ZnSe bulk and thin film materials, in particular making p-type ZnSe and n-type ZnTe, has historically been difficult due to compensation from native defects [15]. But some success has been achieved in thin films via molecular beam epitaxy [16] and in nanowires via chemical vapor deposition [17, 18]. These nanowires are typically limited in length to tens of micrometers. For integration of individual devices into functional circuits, nanostructures with greater lengths and higher aspect ratios are much desired. In this work, we report a method of synthesizing and *ex situ* doping of ZnTe nanoribbons and ZnSe nanowires with extremely large aspect ratios. The lengths of ZnTe nanoribbons are up to hundreds of micrometers and of ZnSe nanowires are up to a few millimeters. Our *ex situ* doping using Cu ion immersion [6] results in successful p-type doping of ZnTe and ionic conduction in ZnSe. These ultra-long, single-crystal, *ex situ* doped group II–VI nanostructures could enable a wide range of studies of integrated electrical, optoelectronic, or photonic devices.

1. Experimental

1.1 Synthesis

ZnTe and ZnSe nanostructures were synthesized by gold-catalyzed vapor transport from ZnTe and ZnSe (Aldrich 99.99%) powder sources, respectively. Oxidized silicon wafers were functionalized, and then covered with 20 nm Au colloids (Aldrich). The source powders were placed at the center of a 1" tube furnace, with the growth substrates downstream. After repeated flushing with Ar to

remove residual oxygen, the nanoribbons and nanowires were grown for 1 h under flowing Ar. Optimal growth source temperature (T), pressure (P), time (t), and carrier gas flow rate (k_{flow}) for ZnTe nanoribbons were $T = 800^{\circ}\text{C}$, $P = 10$ torr, $t = 1$ h, and $k_{\text{flow}} = 50$ standard cubic centimeters per minute (sccm). For ultra-long ZnSe nanowires, $T = 1050^{\circ}\text{C}$, $P = 10$ torr, $t = 1$ h, and $k_{\text{flow}} = 100$ sccm.

1.2 Structural characterization

The morphology and structure of synthesized nanostructures were studied by a Zeiss Gemini Ultra-55 Analytical scanning electron microscope (SEM) equipped with an energy dispersive X-ray spectroscopy (EDX) system, X-ray diffraction (Siemens D5000), and transmission electron microscopy (TEM, JEOL 2100F). For TEM studies, the nanowires were dispersed in isopropanol and deposited on a lacey carbon film supported on a Cu grid.

1.3 Doping

For *ex situ* doping, the nanoribbons and nanowires were transferred to SiO₂ substrates. The substrates were immersed in an aqueous Cu(NO₃)₂ solution [6, 19, 20]. They were subsequently rinsed in de-ionized (DI) water and dried with compressed air. The samples were annealed at 400 °C under vacuum. The conditions used for ZnTe and ZnSe are given in Table 1. Two-probe and four-probe devices were fabricated on single nanoribbons or nanowires by photolithography and contact metals were deposited by electron-beam evaporation.

2. Results and discussion

2.1 ZnTe nanoribbons

Typical synthesized ZnTe nanoribbons ranged in size

Table 1 Cu-doping conditions and contact metal used

Material	Cu(NO ₃) ₂ in 150 mL DI-water (mg)	Solution temperature (°C)	Immersion duration (min)	Annealing temperature /time (°C/min)	Contact metal (nm)
ZnTe	50	25	0, 5, 10, 15, 20	400/20	Ni/Au 15/240
ZnSe	800	60	0, 5, 10, 30, 60	400/60	Cu/Au 20/200

from 50–200 μm in length and 1–10 μm in width, and were approximately 100 nm thick. As seen in the SEM image (Fig. 1(a)), the nanoribbons were tapered, with the wider regions closer to the substrate. Au-rich balls can be found at the narrow ribbon tips (Fig. 1(c)), and their presence was confirmed by EDX spectroscopy. X-ray diffraction confirms that the nanoribbons are face-centered cubic (JCPDS-15-0746) (Fig. 1(b)). High-resolution TEM (HRTEM) shows that the major axis of the nanoribbon goes along [311] (Figs. 1(c) and 1(d)). The wide bounding facet of the nanoribbons is (110). Selected area electron diffraction (SAED) patterns (inset in Fig. 1(d)) along the length of the nanoribbons have identical orientation, indicating the single-crystallinity of the nanoribbons. These ZnTe nanoribbons have a strong and narrow band-edge emission peak at 2.25 eV recorded by micro-photoluminescence at room temperature (not shown), as well as a less prominent broad red luminescence that is commonly attributed to oxygen impurities.

Previous reports of tapered nanoribbons grown by vapor transport attribute the morphology to high source and substrate temperatures; the first increases the amount of molecules in the vapor and the second enhances the surface mobility of adsorbed molecules, allowing side growth and forming the ribbons [21].

The length of the nanoribbons is controlled by the competition between side-wall and catalyst-enabled growth. For lower growth temperatures, molecules are more likely to be incorporated at nearby sites forming ribbons, rather than moving to the catalyst and extending the length.

These high aspect-ratio nanostructures provide a large surface area to volume ratio for fast *ex situ* doping and a convenient topology for defining electrical contacts, as was done by photolithography and subsequent metal deposition. The Ni/Au contacts were ohmic, exhibiting linear current–voltage (I – V) characteristics. With increasing Cu immersion time, the resistivity of the nanowires decreased from $10^5 \Omega\cdot\text{cm}$ for the undoped case to nearly $1 \Omega\cdot\text{cm}$ for the highly Cu-doped samples (Fig. 2). In comparison to the un-annealed sample, vacuum annealing at 400 °C causes a slight increase in resistivity. Indeed, vacuum anneals have been shown to decrease the crystal quality of ZnTe [22]. The undoped nanoribbons have two orders of magnitude higher resistivity than reported values for comparable nanostructures [18], but the properties of our Cu-doped nanoribbons agree well with those of doped nanowires [6]. The trend of decreasing resistivity with immersion time is in line with values obtained from similarly treated

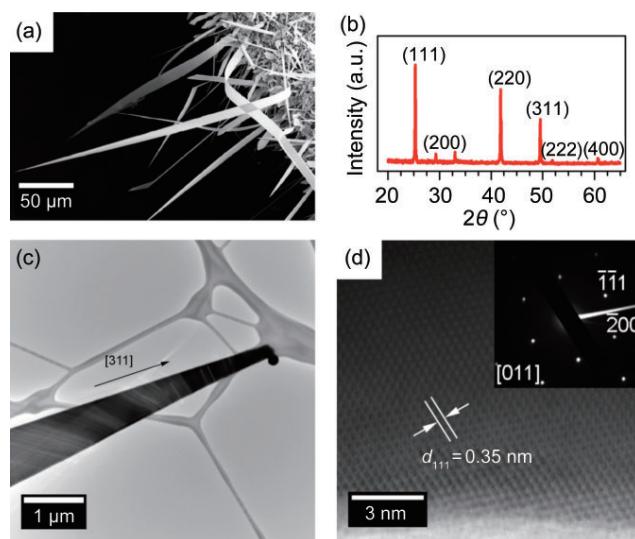

Figure 1 (a) SEM image of ZnTe nanoribbons as grown. (b) XRD pattern obtained from the as-grown chip, indexed to zinc blende ZnTe. (c) Low magnification TEM image of a ZnTe nanoribbon at a tapered region with Au catalyst tip still attached. (d) High-resolution TEM image with corresponding SAED (inset)

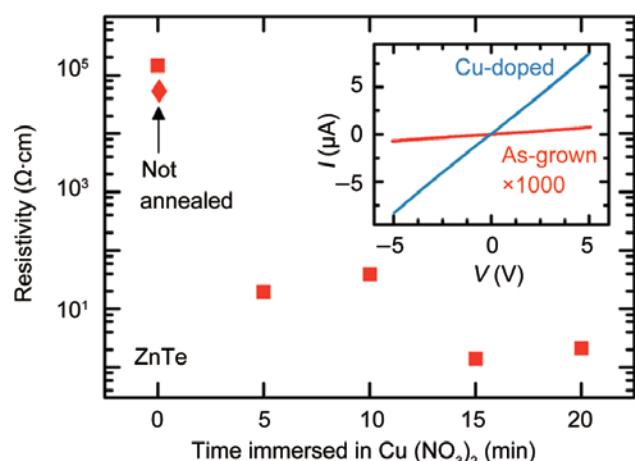

Figure 2 Resistivity of ZnTe nanoribbons versus immersion time in the $\text{Cu}(\text{NO}_3)_2$ solution. The samples were vacuum annealed at 400 °C for 20 min, except for a control case which was neither immersed nor annealed. (Inset) Linear I – V curves from an as-grown ZnTe nanoribbon and another which had been immersed for 20 min. The as-grown signal has been magnified by 1000. The nanoribbon segment measured is approximately 5 μm in width, 100 nm in thickness, and 20 μm in length

thin films [19, 20].

It is well established that Cu sitting substitutionally on Zn sites in ZnTe creates an acceptor level 149 meV above the valence band maximum [23]. As expected, both doped and undoped nanoribbons exhibit p-type behavior, with slightly enhanced conduction on applied negative gate voltage (not shown). It has been proposed that the copper ions are incorporated through an ion exchange process with Zn at the surface, leading to the development of a Cu surface layer which eventually blocks the incorporation of additional Cu [19]. Based on optical transmission studies, vacuum annealing at 400 °C is sufficient to diffuse Cu throughout a 500 nm film [19]. In addition to occupying Zn sites, Cu dopants are reported to accumulate at grain boundaries and Te-inclusions [24]. However, our nanoribbons should not have such doping inhomogeneity due to their nanoscale dimensions and single-crystal nature.

2.2 ZnSe nanowires

Growth substrates of ZnSe nanowires emerged covered with a bright yellow mat of nanowires, even more brilliantly colored than the starting ZnSe source powder (Fig. 3(d)). Radii vary widely from 30 nm to several microns, and can have lengths up to a few millimeters. These extreme lengths lead to spectacular fields of nanowires when imaged by SEM and are visible even by the naked eye (Figs. 3(a) and 3(d)). The longer wires tend to be faceted and wider. Aspect ratios of length versus diameter of up to 10 000 have been found. As a comparison, typical lengths of ZnSe nanowires grown by vapor transport have been previously reported to be a few to tens of microns [10, 12–14], with similar diameters to ours. While ZnSe nanowires grown by molecular beam epitaxy (MBE) are generally smaller in diameter (20–50 nm), their aspect ratios are limited by lengths of only 1–2 μm [25]. In addition, the nanowires are constant in diameter along their length, as demonstrated by Fig. 3(e). XRD spectra of as-grown ZnSe nanowires show that the predominant polytype is zinc blende (JCPDS 37-1463), although there may be a small percentage of wurtzite (JCPDS 80-0008) (Fig. 3(b)). Au-tips are also visible at the top of some nanowires, as can be expected from the Au-catalyzed vapor-

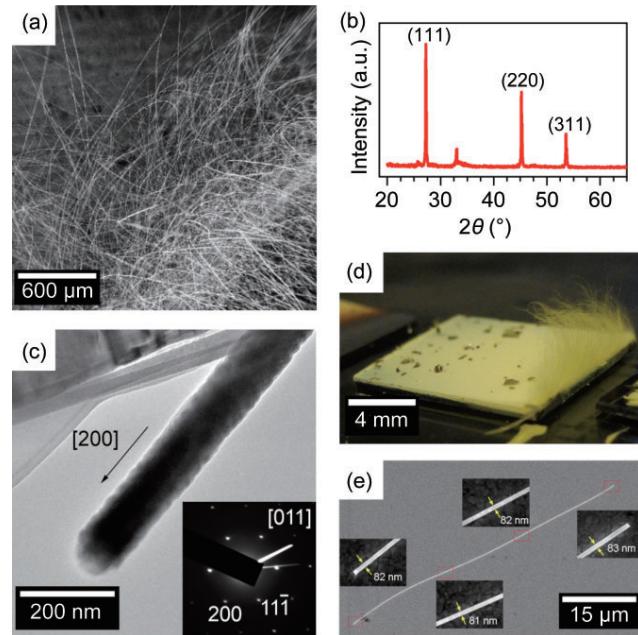

Figure 3 (a) SEM image of ZnSe nanowires as grown. (b) XRD pattern obtained from nanowires on the as-grown substrate, indexed to zinc blende ZnSe. (c) TEM image of a ZnSe nanowire with associated SAED (inset). (d) Photograph of growth substrate, where the mm-long nanowires were grown on the upstream edge. (e) SEM image of a highly uniform ZnSe nanowire transferred onto an Au/Si substrate. The wire was broken during transfer, and is therefore shorter than as-grown structures. (Insets) SEM images of the endpoints and two middle segments

liquid–solid (VLS) growth.

Ultra-long nanowires of Si have been grown via VLS using Si_2H_6 as opposed to the more common SiH_4 to overcome the rate-limiting step of precursor decomposition [26]. However, growth of ultra-long group II–VI nanowires has not been reported. In our case, increasing growth time at lower growth temperatures did not produce such ultra-long nanowires. We therefore attribute the growth of ultra-long ZnSe nanowires to the elevated source temperature (1050 °C) compared with other reports (950 °C), which provides sufficient vapor supply, and the elevated substrate temperature (780 °C) compared with other reports (650–725 °C), which increases surface mobility of adsorbed adatoms on nanowire side-walls, allowing them to rapidly diffuse to the Au-catalyst. Variations in the growth parameters, including decreasing growth temperature or adding a Zn source, also produce ZnSe nanowires; however, they do not reach the extreme lengths produced

under the optimal conditions. Room-temperature micro-photoluminescence shows strong broad luminescence near 2.0 eV and very weak band-edge luminescence near 2.65 eV. In previous reports of ZnSe nanowires, it was found that higher growth temperatures resulted in a higher prevalence of structural defects and thus more intense defect luminescence at room temperature [27]. This may be the reason for the high ratio of defect-to-band-edge luminescence in our nanowires.

The electrical response of Cu-doped ZnSe nanowires developed non-linearity with increasing Cu-ion immersion. Previous reports of undoped, vapor-transport grown ZnSe nanowires show resistivity ranging from 1 to 105 $\Omega\cdot\text{cm}$ [17, 28], which reflects the importance of growth conditions to the electrical quality. Our undoped ZnSe nanowires, both as-grown and annealed, show linear $I-V$ characteristics with resistivities in the range 0.1–1 $\Omega\cdot\text{cm}$. After Cu-immersion, we saw no obvious improvement in conductivity in contrast to the ZnTe case; instead, a hysteretic resistive switching effect appeared, as shown in the inset of Fig. 4. In the switching behavior observed in oxide memristors [29], the device starts with a high-resistance state, and then sweeps back through a low resistance state. In contrast, in our Cu-doped ZnSe nanowire devices the hysteresis loop starts at a low-resistance state, and abruptly changes over to a high-resistance state when swept to a positive threshold bias. The switch occurs between 0.3 and 0.5 V, varying slightly from device to device. When returning to zero bias and sweeping to negative bias, the nanowire behaves nearly symmetrically, starting in a low resistance and transferring to a higher-resistance state. A full understanding of the mechanism of such a resistance switching in Cu-doped ZnSe needs further investigation. Previous work in Cu-doped ZnSe highlights the intricacies involved in making Cu dopants active in ZnSe. Cu-immersion of polycrystalline ZnSe thin films, similar in method to this work, incorporated up to 1 wt% Cu, causing the resistivity to drop eight orders of magnitude [30]. However, for co-evaporated 20% Cu films, *ex situ* annealing made the film non-conductive [31]. 1% Cu doping of ZnSe from the melt also showed an

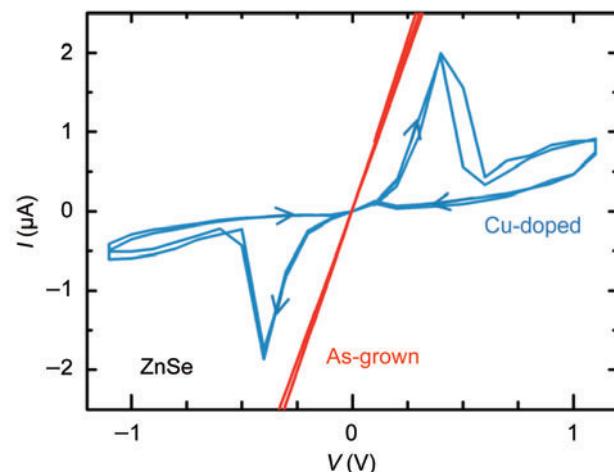

Figure 4 Typical $I-V$ curves of as-grown and Cu-doped (30 min) ZnSe nanowires. The nanowire segment measured is approximately 100 nm in diameter and 4 μm in length

increase in resistivity with increased Cu content [32]. It has been suggested that due to the multi-valence of Cu in ZnSe, it is difficult to tune the Fermi level to make it highly conductive, since the Fermi level can be pinned between Cu deep levels at 0.72 and 0.35 eV above the valence band maximum [33].

3. Conclusions

Crystalline ZnTe nanoribbons with lengths up to a millimeter and ZnSe nanowires with lengths exceeding several millimeters have been synthesized using the vapor transport method. We identified a narrow window of synthesis conditions that allow growth of such nanostructures with extreme aspect ratios. Utilizing a simple ion-immersion method, we *ex situ* doped these nanostructures with Cu. Successful p-type doping was achieved in ZnTe nanoribbons where the resistivity was reduced by five orders of magnitude. Cu doping of ZnSe introduced a resistive switching effect, an electrical process involving ionic conduction possibly activated by the incorporation of multi-valent Cu dopants. Combined with their advanced optical and electrical properties, these ultra-long, single-crystal, *ex situ* doped group II–VI nanostructures could enable studies of nanostructure-based circuits integrating multiple electrical, optoelectronic, or photonic components.
